Revised October 2001

If we want to find the shortest plan, then usually, we try plans of length 1, 2, . . . , until we find the first length for which such a plan exists. When the planning problem is difficult and the shortest plan is of a reasonable length, this linear search can take a long time; to speed up the process, it has been proposed to use binary search instead. Binary search for the value of a certain parameter \( x \) is optimal when for each tested value \( x \), we need the same amount of computation time; in planning, the computation time increases with the size of the plan and, as a result, binary search is no longer optimal. We describe an optimal way of combining planning algorithms into a search for the shortest plan – optimal in the sense of worst-case complexity. We also describe an algorithm which is asymptotically optimal in the sense of average complexity.

Keywords: Planning; Optimal planning

1. Introduction

Since Kautz and Selman’s paper\(^9\) on satisfiability based planning there has been several papers\(^10,15,4,5,16,13,14,11\) on planning through finding models of a logical theory. Most of these papers focus on finding a plan of a given length; see also\(^17,7,2,6,12\). If we want to find the shortest plan, then usually, we try plans of length 1, 2, . . . , until we find the first length for which such a plan exists. When the planning problem is difficult and the shortest plan is of a reasonable length, this linear search can take a long time; to speed up the process, it has been often mentioned – as in\(^13\), that binary search should be used instead.

Binary search for the value of a certain parameter \( p \) is optimal when for each tested value \( p \), we need the same amount of computation time (see, e.g.,\(^3\)). In planning, the computation time drastically increases with the size of the plan. As a result, as we will see, binary search is no longer optimal.

In this paper, we describe an optimal way of combining planning algorithms into a search for the shortest plan – optimal in the sense of worst-case complexity. We
also describe an algorithm which is asymptotically optimal in the sense of average complexity.

2. Towards Formalization of the Problem

We assume that we have a sequence of planning algorithms, i.e., that for every integer \(k\) from 1 to some upper bound \(N\), we have an algorithm \(A_k\) which, given a planning problem, looks for a plan of length \(k\) and returns either such a plan or, if a plan of this length does not exist, a message that no such plan is possible.

We also assume that if for some planning problem, there exists a plan \(p\) of length \(k\), and \(l > k\), then, by adding “dummy” actions, we can turn a plan \(p\) into a new plan of length \(l\); as a result, for every \(l > k\), the algorithm \(A_l\) will discover some plan for this problem. (If we want to avoid dummy actions, then, alternatively, we can assume that an algorithm \(A_k\) looks for a plan of length \(\leq k\))

We want to combine the algorithms \(A_1, \ldots, A_N\) into a single algorithm which would either find the shortest plan of length \(\leq N\), or return a message saying that no plan of length \(\leq N\) can solve the given problem. In this combination, we start with one of the algorithms \(A_k\), then, depending on the outcome of \(A_k\), apply some other algorithm \(A_{ks}\), etc. Two examples of such combinations are linear search and binary search:

- In linear search, we start with \(A_1\) (\(k_1 = 1\)); then, if \(A_1\) did not find a plan, we proceed to \(A_2\), etc.

- In binary search, we start with applying \(A_{[N/2]}\); if this algorithm \(A_{[N/2]}\) finds a plan, we then try \(A_{[N/4]}\), otherwise, we apply \(A_{[3N/4]}\), etc.

We want to find a combination for which the worst-case computation time is the smallest possible. Let us fix a class of planning problems, and let \(c_k\) denote the worst-case computation time of an algorithm \(A_k\) on problems from this class. For each combination algorithm \(C\), and for each actual size \(s\), we can define the worst-case computation time \(T(C,s)\) of the combination \(C\) on such planning problems by adding the times \(c_k\) for all the algorithms \(A_k\) which are used for the planning problems with the shortest plan of size \(s\). Then, we can define the worst-case complexity of the combination \(C\) as the largest of the values \(T(C,1), \ldots, T(C,N)\).

For example, for linear search \(C_{lin}\), when \(s = 1\), we only apply \(A_1\), so we need time \(T(C_{lin},1) = c_1\); when \(s = 2\), we apply both \(A_1\) and \(A_2\), so the time is \(T(C_{lin},2) = c_1 + c_2\), etc. The worst-case computation time is when \(s = N\), then this time is equal to \(T(C_{lin}) = T(C_{lin},N) = c_1 + \ldots + c_N\). For binary search, we will have to similarly compare \(c_{[N/2]} + c_{[N/4]} + \ldots\) with \(c_{[N/2]} + c_{[3N/4]} + \ldots\), etc.

Which combination \(C\) is optimal depends on the values \(c_k\). If \(c_k = \text{const.}\), then binary search is the best combination algorithm\(^3\). In general, however, \(c_k\) grows with \(k\). Planning is known to be an NP-hard problem (see, e.g.,\(^\text{6,1}\)), and so we would expect the time \(c_k\) to grow at least exponentially with \(k\) (i.e., that \(c_k \geq 2^k\) and \(c_{k+1}/c_k \geq 2\)). Our preliminary experiments show that this is probably indeed
the case: when we computed $c_k$ as the largest time on some small set of problems, we got an exponential growth.

For exponentially growing $c_k$, the following algorithm is optimal:

3. **Optimal Combination of Planning Algorithms Which Search for Plans of Different Sizes**

**Combination Algorithm** $C_1$, ("One step forward, two steps back")

- First, apply the algorithm $A_{N-1}$.
- The second step depends on whether there exists a plan of size $N - 1$. If no such plan exists, we then apply $A_N$:
  - if $A_N$ finds a plan, this is the shortest plan, so we stop;
  - if $A_N$ does not find a plan, then no plan of size $\leq N$ is possible, so we stop.

If there is a plan of size $N - 1$, then we apply $A_{N-3}$.

- The third step depends on whether there exists a plan of size $N - 3$. If no such plan exists, we then apply $A_{N-2}$:
  - if $A_{N-2}$ finds a plan, this is the shortest plan, so we stop.
  - if $A_{N-2}$ does not find a plan, then the plan produced by $A_{N-1}$ is the shortest possible, so we stop.

If there is a plan of size $N - 3$, then we apply $A_{N-5}$.

- So, if after applying $A_{N-3}$ we have not yet found the shortest plan, we apply $A_{N-5}$, and then, depending on the result, $A_{N-4}$ or $A_{N-6}$. If we are not done yet, we apply $A_{N-7}$, and then, depending on the result, $A_{N-6}$ or $A_{N-8}$, etc.

We will prove that this combination algorithm $C_1$ is optimal, and that it is optimal not only when the growth is exactly exponential ($c_k = 2^k$), but also for the case when the growth is approximately exponential:

**Definition 1.** Let $q = 1.325 \ldots$ denote a solution to the equation $q^3 = q + 1$. We say that a sequence $c_k$ is approximately exponential if for all $k$, we have $c_{k+1}/c_k \geq q$.

**Theorem 1.** If a sequence $c_k$ is approximately exponential, then, of all possible combination algorithms, the Algorithm $C_1$ has the smallest possible worst-case computation time: $T(C_1) = \min_C T(C)$.

**Proof.** To prove this theorem, we will prove two statements: first, that for $C_1$, we have $T(C_1) = T(C_1, N) = c_N + c_{N-1}$, and second, that for every other combination algorithm $C$, we have $T(C) \geq c_N + c_{N-1}$. From these two statements, we can conclude that $T(C) \geq T(C_1)$ for all $C$ and therefore, that $C_1$ is indeed optimal.
The second statement is the easiest to prove: if the actual size is \( s = N \), then the combination algorithm \( C \) has to produce a plan of size \( N \), and the only way to produce such a plan is to apply the algorithm \( A_N \). To prove that this is indeed the shortest plan, we need to prove that no plan of size \( N - 1 \) exists; for this, we must apply the algorithm \( A_{N-1} \). Thus, for \( s = N \), we must apply at least two algorithms \( A_N \) and \( A_{N-1} \). As a result, the corresponding value \( T(C, N) \) has to be \( \geq c_N + c_{N-1} \). Therefore, \( T(C) = \max_s T(C, s) \geq T(C, N) \geq c_N + c_{N-1} \). The statement is proven.

Let us now prove the first statement. From the description of the algorithm \( C_1 \), we see that for \( s = N \) and \( s > N \), we have \( T(C_1, s) = c_{N-1} + c_N \); for \( s = N - 2 \) and \( s = N - 2k \), we have \( T(C_1, s) = c_{N-1} + c_{N-3} + c_{N-2} \), etc. In general, for \( s = N - (2k - 1) \) and \( s = N - 2k \), we have \( T(C_1, s) = c_{N-1} + c_{N-3} + \ldots + c_{N-(2k+1)} + c_{N-2k} \). To prove that \( T(C_1, N) \) is the largest of these values, we will prove that for every \( k \geq 0 \),

\[
T(C_1, N - (2k + 2)) \leq T(C_1, N - 2k);
\]  

then, by induction, we will be able to conclude that \( T(C_1, s) \leq T(C_1, N) = c_N + c_{N-1} \). Substituting the above explicit expressions for \( T(C_1, s) \) instead of both sides of the desired inequality (1), and canceling equal terms on both sides, we conclude that this inequality is equivalent to the following one: \( c_{N-(2k+3)} + c_{N-(2k+2)} \leq c_{N-2k} \). If we divide both sides of this inequality by \( c_{N-(2k+3)} \), we get an equivalent inequality \( 1 + q_1 \leq c_{N-2k}/c_{N-(2k+3)} \), where we denoted \( q_1 = c_{N-(2k+3)}/c_{N-(2k+3)} \). Similarly, we can represent \( c_{N-2k}/c_{N-(2k+3)} \) as \( q_1 \cdot q_2 \cdot q_3 \), where we denoted \( q_2 = c_{N-(2k+1)}/c_{N-(2k+2)} \) and \( q_3 = c_{N-2k}/c_{N-(2k+1)} \). Since \( c_k \) is approximately exponential, we have \( q_i \geq q \) for all \( i \). In terms of \( q_i \), the desired inequality takes the form \( 1 + q_1 \leq q_1 \cdot q_2 \cdot q_3 \), or, equivalently, \( 1 \leq q_1 \cdot (q_2 \cdot q_3 - 1) \). This inequality can already be proven. Namely, since \( q_i \geq q > 1 \), and \( q^3 + q = 1 \), we have \( q_1 \cdot (q_2 \cdot q_3 - 1) \geq q \cdot (q^2 - 1) = q^3 - q = 1 \). The inequality is proven, and hence, the first statement is also true. Thus, the theorem is proven.

Comment. In our considerations, we estimated the computation time of each algorithm \( A_k \) by its worst-case computation time \( c_k \). The actual computation time of applying \( A_k \) depends on the actual size of the plan: e.g., if we apply a program \( A_N \) to the planning situation in which the size of the actual plan is equal to 1, we expect \( A_N \) to run much faster than on the cases when the actual size of the plan is equal to \( N \). To take this difference into account, let us denote, by \( c_{k,s} \), the worst-case computation time of the program \( A_k \) on planning problems in which the actual size of the plan is \( s \). It is reasonable to assume that the value \( c_{k,s} \) is monotonically non-decreasing with \( s \). We also assume that for all values \( s > k \) (for which \( A_k \) cannot find the plan), the value \( c_{k,s} \) is the same and equal to \( c_{k,k} \); then, \( c_k = \max_s c_{k,s} = c_{k,k} \).

In this new model, for each combination algorithm \( C \) and for each actual plan size \( s \), we define \( \tilde{T}(C) \) as the largest of the values \( \tilde{T}(C, s) \), where \( \tilde{T}(C, s) \) is defined as the sum of the values \( c_{k,s} \) corresponding to all the algorithms \( A_k \) which were called in the process of running \( C \).
One can see that, in effect, the above proof of Theorem 1 also proves that the algorithm $C_1$ is optimal under the new definition as well, i.e., that $\overline{T}(C_1) \leq \overline{T}(C)$ for any other combination algorithm $C$.

4. Average-Case Computation Time: Towards Formalization

In the previous section, we described a combination algorithm for which the worst-case computation time is the smallest possible. In this combination algorithm, we start with checking for a plan of size $N - 1$. In some real-life situations, we know that most probably, the actual plan is long; in such situations, starting with plans of (almost) maximum possible size $N - 1$ would be, in most cases, a waste of computation time. In general, if we know the probabilities $P(s)$ of different values of the actual size, then, instead of looking for a combination algorithm $C$ with the smallest worst-case computation time $T(C) = \max_s T(C, s)$, it is reasonable to look for a combination algorithm $C$ with the smallest possible value of the average-case computation time $T_{av}(C)$.

This average-case computation time can be defined as $T_{av}(C) = \sum_s P(s) \cdot T_{av}(C, s)$, where the average time $T_{av}(C, s)$ can be defined as a sum of average-case computation times $c_k^w$ of applying algorithms $A_k$ which are called in the process of applying the combination algorithm $C$ to the case when the actual plan size is $s$.

For small $N$, we can find the best possible combination algorithm by exhaustive search: namely, we can enumerate all possible combination algorithms, compute the value $T_{av}(C)$ for all of them, and find the combination algorithm $C$ for which this value is the smallest possible. When $N$ increases, the number of all possible combination algorithms increases exponentially and therefore, we cannot try them all. It is therefore desirable to find a method for optimal combination when $N$ is large.

In this paper, we present an asymptotically optimal algorithm $C$ for solving this problem, i.e., an algorithm for which, as $N \to \infty$, the value $T_{av}(C)$ gets closer and closer to the optimal value $\min_C T_{av}(C)$. To find this algorithm, let us describe this problem in an asymptotic form.

We want to find a plan of size $s$ which can take any value from 0 to $N$ (0 means that the initial condition already satisfies the goal, so no actions are necessary). Let us describe the size $s$ by a normalized size $x = s/N$ which takes $N + 1$ possible values $0, 1/N, \ldots, 1$ from the interval $[0, 1]$. For each value $k$ from 0 to $N$, we know the average-case computation time $c_k^w$ of running the algorithm $A_k$ which looks for a plan of size $k$ (i.e., of normalized size $k/N$). We will describe this computation time as function of a normalized size: $c(k/N)$ is defined as $c_k^w$. A typical behavior is when this computation time grows exponentially with $k$, i.e., when $c_k^w = a \cdot b^k$ for some constants $a$ and $b$; in this case, for $x = k/N$, we have $k = x \cdot N$ and $c(x) = a \cdot b^{x \cdot N}$. This expression can be naturally defined for arbitrary values $x \in [0, 1]$; as a result, we get a monotonically non-decreasing function $c : [0, 1] \to R$ which extrapolates the values $c(k/N)$.

Similarly, we can reformulate the probabilities $P(s)$ in terms of normalized size
\( s/N \), as \( P_n(s/N) = P(s) \). For the interval \([0,1]\), it is reasonable to talk about the \textit{probability density} \( \rho(x) \) such that the probability \( P_n(s/N) \) to have a normalized size from the interval \([s/N,(s+1)/N]\) is equal to \( \int_{s/N}^{(s+1)/N} \rho(x) \, dx \). In principle, we can define \( \rho(x) \) as \( P_n(s/N)/(1/N) \) for all \( x \in [s/N,(s+1)/N] \), but more reasonably, if we have an analytical expression for \( P_n(x) \), then we can extrapolate it to an analytical expression for the density function \( \rho(x) \).

Originally, we have no information about the size or the normalized size of the desired plan; this normalized size can take any value from the interval \([0,1]\), or any value \( > 1 \). Since by using algorithms \( A_k \) with \( k \leq N \), we cannot determine the actual size of the plan if this size is larger than \( N \) (i.e., if \( s/N > 1 \)), we will describe this situation by saying that the actual size of the shortest plan belongs to the “extended” interval \([0,1+]\), where “1+” indicates that values \( > 1 \) are also possible.

We want to combine the algorithms \( A_k \) corresponding to different values of normalized size \( x = k/N \) into a single algorithm which would either find the shortest plan of normalized length \( \leq 1 \), or return a message saying that no plan of normalized length \( \leq 1 \) can solve the given problem. In this combination \( C \), we start with some normalized size \( x \in [0,1] \) and check whether there exists a plan of this normalized size. If such a plan exists, then we know that the actual normalized size belongs to the interval \([0,x]\); if a plan of normalized size \( x \) does not exist, then we know that the actual size of the shortest plan belongs to the interval \([x,1+]\). In each of these cases, at the next step, we select a value within the corresponding interval and check whether there exists a plan with this particular value of normalized size, etc.

For example, in binary search, we first check \( x = 1/2 \); then, depending on the result of this first check, we check for the values \( x = 1/4 \) or \( x = 3/4 \), etc.

Our goal is to find the actual size \( s \) of the shortest plan. In terms of the normalized size \( x = s/N \), we want to find \( x \) with the accuracy of \( 1/N \), i.e., we want to find an interval of width \( < 1/N \) which contains the desired value \( x = s/N \). In the following text, we will denote \( 1/N \) by \( \varepsilon \); then, the asymptotic of \( N \to \infty \) corresponds to \( \varepsilon \to 0 \).

Now, we are ready to formulate the problem in formal terms:

- We have a monotonically non-decreasing function \( c(x) \) from \([0,1]\) to real numbers; this function describes the cost of checking for a plan of normalized size \( x \).

- We also have a probability density \( \rho(x) \); this probability density describes relative frequencies of plans of different size.

The goal of a combination algorithm is to find the actual normalized size \( x \) with the given accuracy \( \varepsilon > 0 \). For each such algorithm, and for each actual value \( x \) of normalized size, we can define the computation time \( t(C,x) \) as the sum of all the values \( c(x) \) for all points \( x \) for which the corresponding algorithm \( A_k \) was invoked. Then, we use our knowledge of the probabilities of different sizes to define
the average-case computation time $t(C)$ as the average value of $t(C, x)$:

$$ t(C) = \int_0^1 t(C, x) \cdot \rho(x) \, dx. $$

We want to choose the combination algorithm $C$ for which the average computation time $t(C)$ is (asymptotically, when $\varepsilon \to 0$) the smallest possible.

5. Average-Case Computation Time: Main Result

We will prove that the following algorithm $C_2$ is asymptotically optimal:

**Combination Algorithm $C_2$**. In the beginning, we only know that the normalized size $x$ of the shortest plan is somewhere in the interval $[x^-, x^+]$, where $x^- = 0$ and $x^+ = 1$.

On each step of this algorithm, whenever we have the interval $[x^-, x^+]$, we select a checking point $x \in (x^-, x^+]$ which divides the integral $\int_{x^-}^{x^+} \rho(z) \cdot c(z) \, dz$ into two equal halves: $\int_{x^-}^{x} \rho(z) \cdot c(z) \, dz = \int_{x}^{x^+} \rho(z) \cdot c(z) \, dz$. Then:

- if there is a plan of normalized size $x$, then we replace $x^+$ by $x$: $[x^-, x^+] := [x^-, x]$;
- otherwise, we replace $x^-$ by $x$: $[x^-, x^+] := [x, x^+]$.

We continue these iterations until we get $x^+ - x^- < \varepsilon$.

**Theorem 2.** When $\varepsilon \to 0$, the algorithm $C_2$ has (asymptotically) the smallest possible average-case computation time $t(C_2)$.

**Proof: Main Idea,** Let us start with estimating the average-case computation time for the binary search algorithm $C_b$.

At the first step of binary search, we check for $x = 0.5$. As a result of this first step, the interval $[x^-, x^+]$ containing the actual normalized size $x$ is equal either to $[0, 0.5]$, or to $[0.5, 1+]$. The corresponding computation time is equal to $P([0, 1]) \cdot c(0.5)$, where, for arbitrary $a$ and $b$, $P([a, b])$ denotes $\int_a^b \rho(x) \, dx$.

At the second step, we check $x = 0.25$ if $s \in [0, 0.5]$ (the probability of which is $P([0, 0.5])$, and we check $x = 0.75$ if $s \in [0.5, 1]$. As a result, we get an interval $[x^-, x^+]$ of width $2^{-2}$. The resulting contribution of the second step to the average computation time is $P([0, 0.5]) \cdot c(0.25) + P([0.5, 1]) \cdot c(0.75)$.

On $k$-th step, the corresponding contribution is equal to $P([0, 2^{-k}]) \cdot c(0.5 \cdot 2^{-(k-1)}) + P([2^{-k}, 2 \cdot 2^{-(k-1)})] \cdot c(1.5 \cdot 2^{-(k-1)}) + \ldots$

After $k$ steps, we end up with an interval of width $2^{-k}$; so, the number $n$ of steps necessary to get an interval of desired width $\varepsilon$ is determined by the equality $2^{-k} \approx \varepsilon$, i.e., $k \sim \log_2 (1/\varepsilon)$.

The sum corresponding to each of these $n$ steps is an integral sum for the integral $\int_0^1 \rho(x) \cdot c(x) \, dx$, and the larger $k$, the closer this sum is to the integral. Thus, this integral is an asymptotic expression for the sum, and asymptotically, the total computation time is equal to the product of this integral and the total number of steps: $t(C_b) \sim (\int \rho(x) \cdot c(x) \, dx) \cdot \log_2 (1/\varepsilon)$.
Let us now use this estimate to find the (asymptotic) average computation time $t(C)$ for an arbitrary combination algorithm $C$. An arbitrary combination algorithm can be characterized as follows. Let us map the first point $x \in (0,1)$ which is checked according to the algorithm $C$ into a point $f(x) = 0.5$ which is first checked in binary search $C_b$. Then, let us map the points $x' \in (0,x)$ and $x'' \in (x,1)$ which are checked next in $C$ (depending on the result of checking for $x$) into, correspondingly, $f(x') = 0.25$ and $f(x'') = 0.75$. In general, let us map every point $x$ which is checked in $C$ into the value $f(x)$ which is checked at the corresponding step of the binary search algorithm $C_b$. As a result, we get a monotonic function $f : [0,1] \rightarrow [0,1]$; let $g(x)$ denote an inverse function to $f$, i.e., $g = f^{-1}$.

Due to our choice of this function, with respect to the new variable $y = f(x)$, the algorithm $C$ is simply a binary search. In this binary search, the computation time $\bar{c}(y)$ corresponding to a value $y$ is equal to $c(x)$ for $x = f^{-1}(y)$, i.e., $\bar{c}(y) = c(g(y))$. Similarly, the probability density $\bar{\rho}(y)$ for $y$ can be determined from the fact that when $y = f(x)$, the probability $\bar{\rho}(y) \cdot dy$ that $y$ is between $y$ and $y + dy$ is equal to the probability $\rho(x) \cdot dx$ for $x = g(y)$ to be between $x = f^{-1}(y)$ and $x + dx = f^{-1}(y + dy) = g(y) + g'(y) \cdot dy$, where $g'(y)$ denotes the derivative of the function $g(y)$. To get an interval of $y$-width $\varepsilon$, we need the number of steps which asymptotically equals to $\log_2(1/\varepsilon) \cdot I$, where $I = \int \bar{\rho}(y) \cdot \bar{c}(y) \, dy$. Substituting the above values for $\bar{\rho}(y)$ and $\bar{c}(y)$, we conclude that $I = \int \rho(x) \cdot c(x) \, dx$ for the new variable $x = g(y)$. In short, to get an interval of $y$-width $\varepsilon$, we need exactly the same average computation time as binary search.

However, this computation time only leads to an interval of $y$-width $\Delta y = \varepsilon$, and we need an interval of $x$-width $\Delta x = \varepsilon$. Thus, we need to narrow down from $\Delta y = \varepsilon$ to $\Delta x = \varepsilon$. Within a narrow interval of width $\Delta y = \varepsilon$, the functions $c(x)$ and $\rho(x)$ do not change much and are asymptotically constant as $\varepsilon \rightarrow 0$. Thus, within such an interval, binary search is the best possible strategy. We know that for a binary search to narrow down an interval $k$ times, we need $\log_2(k)$ steps. Hence, for each $x$, the average number of steps needed for this narrowing is equal to $\log_2(1/f'(x)) = -\log_2(f'(x))$. Therefore, the average computation time for this $x$ is equal to $-\log_2(f'(x)) \cdot c(x)$, and the average over all possible values $x \in [0,1]$ is equal to

$$J = -\int_0^1 \log_2(f'(x)) \cdot \rho(x) \cdot c(x) \, dx. \quad (2)$$

The total average computation time is equal to the binary search time (which does not depend on the choice of the algorithm $C$) plus this time $J$; so, to minimize the total average computation time, it is sufficient to minimize this expression $J$.

We are describing each combination algorithm $C$ by the function $f(x)$, so we must find the function $f(x)$ which minimizes $J$. The only restriction on $f(x)$ is that it should be a mapping from the entire interval $[0,1]$ into the entire interval $[0,1]$, i.e., that we should have $f(0) = 0$ and $f(1) = 1$. Since $\int_0^1 f'(x) \, dx = f(1) - f(0)$,
we can represent this restriction in terms of $f'(x)$ as follows:

$$\int_0^1 f'(x) \, dx = 1. \tag{3}$$

We are, therefore, minimizing (2) under the condition (3). Lagrange multiplier method enables us to reduce this conditional optimization problem to an unconditional optimization problem

$$-\int_0^1 \log_2(F(x)) \cdot \rho(x) \cdot c(x) \, dx + \lambda \cdot \int_0^1 F(x) \, dx \rightarrow \min, \tag{4}$$

where $\lambda$ is a constant (Lagrange multiplier) and $F(x)$ denotes $f'(x)$. Differentiating the left-hand side of (4) with respect to $F(x)$ (see, e.g., 8), and taking into consideration that $\log_2(z) = \ln(z)/\ln(2)$, we get the equation $-\rho(x) \cdot c(x)/(\ln(2) \cdot F(x)) + \lambda = 0$, i.e., $F(x) = f'(x) = \text{const} \cdot c(x) \cdot \rho(x)$. Thus, $f(x) = \text{const} \cdot \int_0^1 \rho(z) \cdot c(z) \, dz$.

In the algorithm $C$, when we make the first division, we select a point $x$ for which $f(x) = 0.5$, i.e., which divides the integral $\int_0^1 \rho(z) \cdot c(z) \, dz$ into two equal halves $\int_0^{x^-} \rho(z) \cdot c(z) \, dz = \int_{x^+}^1 \rho(z) \cdot c(z) \, dz = 0.5$. Similarly, on each step, when we have reached an interval $[x^-, x^+]$, we select a point $x \in (x^-, x^+)$ which divides the integral $\int_{x^-}^{x^+} \rho(z) \cdot c(z) \, dz$ into two equal halves. In short, the optimal algorithm is exactly algorithm $C_2$. The theorem is proven.

**Comment.** From the proof, we can extract the explicit (asymptotic) analytical expression for the computation time of the (asymptotically) optimal combination algorithm $C_2$.

Indeed, the integral in the binary-search expression is simply the average computation time $\langle c \rangle$ of checking for a plan of random size. We can determine the constant in the formula for $f'(x)$ by using the fact that $\int_0^1 f'(x) \, dx = 1$, so this constant is equal to $1/\langle c \rangle$. Thus, the above expression for $f'(x)$ for the optimal combination algorithm $C_2$ takes the form $f'(x) = c_r(x) \cdot \rho(x)$, where $c_r(x) = c(x)/\langle c \rangle$ denotes the “relative” computation time of checking for plans of different normalized size $x$. Thus, the total average-case computation time takes the form

$$t(C_2) = \langle c \rangle \cdot \log_2 \left( \frac{1}{\varepsilon} \right) - \langle c \rangle \cdot \int_0^1 \rho(x) \cdot c_r(x) \cdot \log_2(\rho(x) \cdot c_r(x)) \, dx, \tag{5}$$

where we denote $\varepsilon = 1/N$, $\langle \cdot \rangle = \int_0^1 \rho(x) \cdot c(x) \, dx$, and $c_r(x) = c(x)/\langle c \rangle$.

In particular, when $c(x) = \text{const}$, we get $c_r(x) = 1$, and the second term in the expression (5) turns into the entropy $\int_0^1 \rho(x) \cdot \log_2(\rho(x)) \, dx$ of the probability distribution $\rho(x)$. It is known that the entropy can be defined as, crudely speaking, the smallest number of binary questions which we need to ask to get the exact value. We can therefore view the expression (5) as a natural generalization of the classical notion of an entropy to the case when different questions have different costs (in our case, computation time), and so, instead of simply counting the questions, we count the total cost.
