Abstract—To gauge the risk corresponding to a possible disaster, it is important to know both the probability of this disaster and the expected damage caused by such potential disaster (“expected shortfall”). Both these measures of risk are easy to estimate in the ideal case, when we know the exact probabilities of different disaster strengths. In practice, however, we usually only have a partial information about these probabilities: we may have an interval (or, more generally, fuzzy) uncertainty about these probabilities. In this paper, we show how to efficiently estimate the expected shortfall under such interval and/or fuzzy uncertainty.

I. FORMULATION OF THE PROBLEM

How to gauge risk. In the ideal world, there should be no risk: all engineering designs should be 100% reliable. To achieve such reliability, civil engineers use the record of historic floods, tsunamis, hurricanes, earthquakes, and other natural disasters to estimate the largest possible strength of such a disaster, and design the buildings, bridges, and other structures so that they can withstand such disasters.

The historic experience shows, however, that there is always a possibility that the disaster strength $S$ exceeds the estimated threshold $s_0$: this was the reason why the hurricane Katrina devastated New Orleans, why in 2011, Fukushima nuclear power station in Japan was destroyed by an unusually high tsunami, etc.

Since we cannot have a threshold $s_0$ that would guarantee that the disaster strength never exceeds $s_0$, the next best thing is to select a threshold $s_0$ for which the probability of exceeding $s_0$ does not exceed a given small number $p_0$, i.e., for which, we probability $p \equiv 1 - p_0 \approx 1$, we have $S \leq s_0$.

The choice of the threshold probability $p_0$ depends on the situation. For example:

- for manned space flights, NASA selected $p_0 = 10^{-3}$; smaller values were not feasible because of high uncertainty associated with space flights;
- on the other extreme, for reliability of a cell forming a computer memory, we need $p_0 \ll 10^{-9}$, because otherwise, if we allow $p_0 \gg 10^{-9}$, at least one of the billions of cells will always go wrong.

In addition to knowing the threshold $s_0$, it is also desirable to also know how much damage will come, on average, if this threshold is exceeded. For each possible value $S$ of the corresponding disaster strength, we can estimate the corresponding damage $X$; the stronger the disaster, the larger the damage. Let $x_p$ denote the damage corresponding to the threshold value $s_0$; then, the condition $S \geq s_0$ is equivalent to $X \geq x_p$.

In these terms, the probability that the disaster strength exceeds the threshold $s_0$ is equal to $\text{Prob}(X > x_p)$. In addition to this probability, it is desirable to also know the conditional expectation of the damage under the condition that the disaster strength exceeds the threshold $x_p$, i.e., the value

$$\text{ES}_p \equiv E[X \mid X \geq x_p].$$

The corresponding conditional expectation is known as expected shortfall. These two values:

- the threshold $x_p$, and
- the expected shortfall $\text{ES}_p$;

is how we gauge the risk.

Similar two measures are used in finance to describe the risk that an investment would result in a big loss; see, e.g., [4].

How to estimate the expected shortfall in the ideal case, when we know the probability distribution describing damage. In the ideal case, we know the probability distribution that describes possible values of the damage $X$. A usual way to describe a probability distribution is by describing its cumulative distribution function (cdf) $F(x) \equiv \text{Prob}(X \leq x)$; see, e.g., [6].

In terms of cdf, the probability of exceeding the threshold value $x_0$ is simply equal to $1 - F(x_p)$. Thus, we have $1 - F(x_p) = p_0$ and hence, $F(x_p) = 1 - p_0 = p$. For each probability $p$, the value $x_p$ for which $F(x_p) = p$ is known as the $p$-th quantile. For example:
for $d = 0.5$, we get the median;
for $d = 0.25$ and $d = 0.75$, we get quartiles, etc. In mathematical terms, the function that maps $d$ to $x_d$ is an inverse function to the cdf $F(x)$.

The conditional expectation can then be computed as the ratio
\[ \frac{\int_{x_p}^{\infty} x \ dF(x)}{1 - p}. \tag{1} \]

**In practice, we only have partial information about the probabilities.** In practice, we rarely know the exact values of all the probabilities, we only have partial information about these probabilities. This may mean that, instead of the exact values $F(x)$ corresponding to different values $x$, we only know an interval $[F(x), F(x)]$ that contains the actual (unknown) value $F(x)$. Such situation when, for each $d$, we only know the corresponding intervals, is known as a probability box or, for short, a p-box; see, e.g., [1], [2].

Even more generally, for each $x$, we may have several intervals $[F(x), F(x)]$ corresponding to different degrees of certainty $\alpha \in [0, 1]$, i.e., in effect, a fuzzy number; see, e.g., [3], [5], [7].

**How to gauge risk under such an uncertainty?** For different distributions $F(x) \in [F(x), F(x)]$ within a given p-box, we get different values of quantiles $x_p$ for which $F(x_p) = p$. One can easily check that:

- the smallest value $x_p$ corresponds to the largest values $F(x)$ of the cdf; while
- the largest value $x_p$ corresponds to the smallest values $F(x)$ of the cdf.

Thus, possible values of the quantile $x_p$ form an interval $[x_p, x_p]$ in which $F(x_p) = F(x_p) = p$.

Such quantile intervals are often useful when we perform computations with p-boxes; see, e.g., [1], [2].

We can use this idea to handle the case when we have a fuzzy-valued function $F(x)$, if we take into account the known fact that for all possible computations $y = f(x_1, \ldots, x_n)$ with fuzzy numbers, the alpha-cut
\[ y(\alpha) = \{ y : \mu(y) \geq \alpha \} \]

of the result is equal to the range
\[ f(x_1(\alpha), \ldots, x_n(\alpha)) = \{ f(x_1, \ldots, x_n) : x_i(\alpha) \leq x_i \leq x_i(\alpha), \ldots, x_n(\alpha) \} \]
of the values $f(x_1, \ldots, x_n)$ when each $x_i$ belongs to the corresponding $\alpha$-cut $x_i(\alpha) = \{ x_i : \mu_i(x_i) \geq \alpha \}$; see, e.g., [3], [5].

Thus, to find the $\alpha$-cut of the quantile $x_p$, it is sufficient to compute the interval $[x_p, x_p]$ in situation when each $F(x)$ belongs to the corresponding $\alpha$-cut of the fuzzy number $F(x)$. In other words, from the algorithmic viewpoint, the problem of computing the expected shortfall under fuzzy uncertainty can be indeed reduced to the case of interval (p-box) uncertainty.

**II. Analysis of the Problem**

**Let us find an equivalent expression for $ES_p$.** To find the range of possible values of expected shortfall $ES_p$, let us find an equivalent expression for $ES_p$ that would simplify the computation of this range.

According to formula (1), we have
\[ ES_p = \frac{1}{1 - p} \cdot I, \tag{3} \]

where
\[ I \overset{\text{def}}{=} \int_{x_p}^{\infty} x \ dF(x). \tag{4} \]

Thus:
the expected shortfall $ES_p$ attains its smallest possible value $ES_p$ when the integral $I$ attains its smallest possible value $L_i$ and

- the expected shortfall $ES_p$ attains its largest possible value $ES_p$ when the integral $I$ attains its largest possible value $T$.

The integral $I$ has an infinite upper bound. This integral can be thus represented as a limit of integrals $I_T$ with a finite upper bound $T$ when $T \to \infty$:

$$I = \lim_{T \to \infty} I_T,$$

where

$$I_T = \int_{x_p}^{\infty} x \, dF(x).$$

Thus, for very large $T$, we have $I \approx I_T$.

The integral $I_T$ can be integrated by part:

$$I_T = x \cdot F(x)|_T^x - \int_x^T F(x) \, dx = T \cdot F(T) - x_p \cdot F(x_p) - \int_x^T F(x) \, dx.$$  \hspace{1cm} (7)

For large $T$, we have $F(T)$ practically equal to $1$, so $T \cdot F(T) = T$ and

$$I_T = T - x_p \cdot F(x_p) - \int_x^T F(x) \, dx.$$  \hspace{1cm} (8)

By definition of a quantile $x_p$, we have $F(x_p) = p$, so

$$I_T = T - x_p \cdot p - \int_x^T F(x) \, dx.$$  \hspace{1cm} (9)

One can easily see, from the expression (9), that the integral $I_T$ is a decreasing function of the values $F(x)$. Thus, this integral is the largest when all the values $F(x)$ are the smallest.

What limitations on the values $F(x)$ do we have?

- We have a limitation $F(x) \leq F(x) \leq F(x)$ coming from the fact that we only consider cdfs from a given p-box $[F(x), F(x)]$.
- We also have a limitation $F(x) \geq F(x) = p$, which, for values $x \geq x_p$, comes from the requirement $F(x_p) = p$ and from the fact that each cdf is an increasing function of $x$.

These constraints $F(x) \leq F(x) \leq F(x)$ and $F(x) \geq p$ can be equivalently described by a single constraint

$$\max(F(x), p) \leq F(x) \leq F(x).$$  \hspace{1cm} (10)

Thus, the smallest possible values of $F(x)$ correspond to

$$F(x) = \max(F(x), p).$$  \hspace{1cm} (11)

When $F(x) \geq p$, we have

$$\max(F(x), p) = F(x)$$

and hence $F(x) = F(x)$. As we described earlier, the equality $F(x) = F(x)$ is equivalent to $x = x_p$, thus the condition $F(x) \geq p$ is equivalent to $x \geq x_p$.

On the other hand, when $F(x) < p$, i.e., equivalently, when $x < x_p$, we have $F(x) = F(x)$. Thus,

$$\int_{x_p}^{\infty} F(x) \, dx = \int_{x_p}^{x_p} F(x) \, dx + \int_{x_p}^{\infty} F(x) \, dx = (x_p - x_p) \cdot p + \int_{x_p}^{\infty} F(x) \, dx.$$  \hspace{1cm} (12)

Thus, the expression (9) takes the form

$$I_T = T - x_p \cdot p - \int_{x_p}^{\infty} F(x) \, dx.$$  \hspace{1cm} (13)

The two terms $x_p \cdot p$ and $(x_p - x_p) \cdot p$ can be easily combined into a single term $x_p \cdot p$, so

$$I_T = T - x_p \cdot p - \int_{x_p}^{\infty} F(x) \, dx.$$  \hspace{1cm} (14)

Since $x_p$ is the quantile corresponding to the lower endpoint $F(x)$ of the p-box, we can therefore conclude that the expression (14) is the value of the integral $I_T$ corresponding to $F(x) = F(x)$.

Thus, the largest value of the integral $I_T$ – and hence, of the expected shortfall – is attained when $F(x) = F(x)$.

When does the integral $I_T$ attain its largest possible value? Let us start with the largest possible value. Different cdfs $F(x)$ from the given p-box result, in general, in different values of the integral $I_T$. Let $x_p$ be the value corresponding to the cdf $F(x)$ for which this integral is the largest possible. This means, in particular, that among all cdfs $F(x)$ with the same value of the $p$-th quantile $x_p$ (i.e., for which $F(x_p) = p$), this particular cdf $F(x)$ leads to the largest possible value of the integral $I_T$.

When does the integral $I_T$ attain its smallest possible value? Let us now consider the smallest possible value. Let $x_p$ be the value corresponding to the cdf $F(x)$ for which this integral is the smallest possible. This means, in particular, that among all cdfs $F(x)$ with the same value of the $p$-th quantile $x_p$ (i.e., for which $F(x_p) = p$), this particular
cdf $F^{\text{min}}(x)$ leads to the smallest possible value of the integral $I_T$.

Since the integral $I_T$ is a decreasing function of the values $F(x)$, this integral is the smallest when all the values $F(x)$ are the largest. Under the limitations (10), the largest possible values are $F(x) = F(x)$.

Thus, the smallest value of the integral $I_T$ – and hence, of the expected shortfall $E_S$ – is attained when $F(x) = F(x)$.

### III. Resulting Algorithm

**Problem: reminder.** We want to find the range $[E_S, E_S]$ of possible values of the expected shortfall $E_S$ when cdf $F(x)$ is in the given p-box $[F(x), F(x)]$.

**Conclusion.** The above analysis leads to the following conclusion:

- The largest possible value $E_S$ of the expected shortfall $E_S$ is attained when $F(x) = F(x)$ for all $x$.
- The smallest possible value $E_S$ of the expected shortfall $E_S$ is attained when $F(x) = F(x)$ for all $x$.

Thus, we arrive at the following algorithm:

**Resulting algorithm.**

- First, we compute the expected shortfall $E_S$ corresponding to $F(x) = F(x)$. This shortfall we be the desired upper endpoint $E_S$ of the desired interval $[E_S, E_S]$.
- Then, we compute the expected shortfall $E_S$ corresponding to $F(x) = F(x)$. This shortfall we be the desired upper endpoint $E_S$ of the desired interval $[E_S, E_S]$.

**Comment.** Of course, these two computations, of $E_S$ and $E_S$, do not have to be performed sequentially: if parallel computers are available, we can perform the computation of these two endpoints in parallel.
