Abstract—To more adequately gauge the student’s knowledge, it is desirable to take into account not only whether the student’s answers on the test are correct or not, but also how confident the students are in their answers. For example, a situation when a student gives a wrong answer, but understands his/her lack of knowledge on this topic, is not as harmful as the situation when the student is absolutely confident in his/her wrong answer. In this paper, we use the general decision making theory to describe the best way to take into account the student’s degree of certainty when evaluating the test results.

I. INTRODUCTION

Need to take into account the student’s degree of certainty.
On a usual test, a student provides answers to several questions, and the resulting grade depends on whether these answers are correct.

However, this approach does not take into account how confident the students is in his/her answer.

In real life situations, when a person needs to make a decision, it may happen that a person does not know the correct answer – but it is not so bad if this person realizes that his knowledge is weak on this subject. In this case, he/she may consult an expert and come up with a correct decision. The situation is much worse if a decision maker is absolutely confident in his/her wrong decision.

For example, we do not expect our medical doctor to be perfect, but what we do expect is that when the doctor is not sure, he/she knows that his/her knowledge of this particular medical situation is lacking, and either consults a specialist him/herself or advises the patient to consult a specialist.

From this viewpoint, when gauging the student’s level of knowledge, it is desirable:

- to explicit ask the student how confident he/she is in the corresponding answer, and
- to take this degree of confidence into account when evaluating the resulting grade.

Some tests already solicit these confidence degrees from the students; see, e.g., [4], [6], [8], [9]; see also [3], [8].

How can we take the student’s degree of certainty into account? Once we have the student’s degrees of confidence in different answers, how should we combine these degrees of confidence into a single overall grade?

As of now, the existing combination rules are semi-heuristic. It is therefore desirable to come up with well-justified rules for such combination.

II. HOW TO TAKE INTO ACCOUNT A STUDENT’S DEGREE OF CERTAINTY WHEN EVALUATING THE TEST RESULTS: CASE OF ONE QUESTION WITH TWO ALTERNATIVES

Need to describe how decisions are made: reminder. A natural idea to gauge student’s uncertain knowledge is to analyze how this uncertainty affects the decisions. To be able to perform this analysis, we need to describe what is a reasonable way to make a decision based on the opinion of several uncertain (and independent) experts.

Decision making under uncertainty: general case. According to decision theory, decisions made by a rational agent can be described as follows:

- to each possible situation, we assign a numerical value called its utility, and
- we select an action for which the expected value of utility is the largest possible;

see, e.g., [1], [5], [7], [10].

Let us start with the simplest simplified case. Let us start our analysis with the simplest case, in which:

- we only have one question and
- for this question, there are only two possible alternatives \(A_1\) and \(A_2\).

Let \(P_1\) be the student’s degree of confidence in the answer \(A_1\). Since we assumed that there are only two possible answers, the student’s degree of confidence in the other answer \(A_2\) is equal to \(P_2 = 1 - P_1\).
To gauge the effect of the student’s answer on the resulting decision, let us assume that for each of the two alternatives \(A_1\) and \(A_2\), we know the optimal action.

For example, we have two possible medical diagnoses, and for each of these diagnoses, we know an optimal treatment.

Let \(u_{i,j}\) be the utility corresponding to the case when
- the actual situation is \(A_i\) and
- we use the action which is optimal for the alternative \(A_j\).

In these terms, the fact that the action corresponding to \(A_1\) is optimal for the situation \(A_1\) means that \(u_{1,1} > u_{1,2}\); similarly, we get \(u_{2,2} > u_{2,1}\).

If we know the probabilities \(p_1\) and \(p_2 = 1 - p_1\) of both situations, then we select the action corresponding to \(A_1\) if its expected utility is larger, i.e., if

\[
p_1 \cdot u_{1,1} + (1 - p_1) \cdot u_{2,1} > p_1 \cdot u_{1,2} + (1 - p_1) \cdot u_{2,2},
\]

i.e., equivalently, if

\[
p_1 \geq t = \frac{u_{2,2} - u_{2,1}}{(u_{1,1} - u_{1,2}) + (u_{2,2} - u_{2,1})}. \tag{1}
\]

If the actual situation is \(A_1\), then the optimal action is the one corresponding to \(A_1\). Thus, the above inequality describes when the optimal action will be applied – when our degree of confidence in \(A_1\) exceeds a certain threshold \(t\).

How to estimate the probabilities of different alternatives under expert uncertainty. Let us denote the number of experts by \(n\). Let us assume that for each expert \(k\), we know this expert’s degree of confidence (subjective probability) \(p_{1,k}\) in alternative \(A_1\), and his/her degree of confidence \(p_{2,k} = 1-p_{1,k}\) in alternative \(A_2\).

In general, we do not have prior reasons to believe that some experts are more knowledgeable than others, so we assume that all \(n\) experts are equally probable to be right:

\[
P(k\text{-th expert is right}) = \frac{1}{n}.
\]

Thus, by the law of complete probability, we have

\[
p_1 = \text{Prob}(A_1 \text{ is the actual alternative}) = \sum_{k=1}^{n} P(k\text{-th expert is right}) \cdot P(A_1 | k\text{-th expert is right}),
\]

hence

\[
p_1 = \frac{1}{n} \cdot \sum_{k=1}^{n} p_{1,k}. \tag{2}
\]

How to estimate the student’s contribution to the correct decision. We started with the average of the probabilities of \(n\) experts. Once we add the student as a new expert, with probabilities \(p_{1,n+1} = p_1\) and \(p_{2,n+1} = p_2\), the probability \(p_1\) changes to the new value

\[
p_1' = \frac{1}{n+1} \cdot \sum_{k=1}^{n+1} p_{1,k} = \frac{n}{n+1} \cdot p_1 + \frac{1}{n+1} \cdot P_1. \tag{3}
\]

For large \(n\), this addition is small, so in most cases, it does not change the decision. However:

- sometimes, the increase in the estimated probability \(p_1\) will help us switch from the wrong decision to the correct one, and
- sometimes, vice versa, the new estimate will be smaller than the original one and thus, because of the addition of the student’s opinion, the group will switch from the correct to the wrong decision.

According to the general decision theory ideas, the student’s contribution can be gauged as the expected utility gained by the corresponding change, i.e., as the probability of the positive change times the gain minus the probability of the negative loss times the corresponding loss.

The probability of a gain is equal to the probability that \(p_1 < t\) but \(p_1' \geq t\). Due to (3), the inequality \(p_1' \geq t\) is equivalent to

\[
p_1 \geq t + \frac{1}{n} \cdot t - \frac{1}{n} \cdot P_1.
\]

Thus, the probability of the gain is equal to the probability that the previous estimate \(p_1\) is in the interval

\[
[t + \frac{1}{n} \cdot t - \frac{1}{n} \cdot P_1, t].
\]

For large \(n\), this interval is narrow, so this probability can be estimated as the probability density \(p(t)\) of the probability corresponding to \(p_1\) times the width

\[
\frac{1}{n} \cdot P_1 - \frac{1}{n} \cdot t
\]

of this interval. Thus, this probability is a linear function of \(P_1\).

Similarly, the probability of the loss is also a linear function of \(P_1\) and hence, the expected utility also linearly depends on \(P_1\).

How to gauge student’s knowledge: analysis of the problem. The appropriate measure should be a linear function of the student’s degree of certainty \(P_1\). So, if we originally assign:

- \(N\) points to a student who is absolutely confident in the correct answer and
- 0 points to a student who is absolutely confident in the wrong answer,

then the number of points assigned in general should be a linear function of \(P_1\) that is:

- equal to \(N\) when \(P_1 = 1\), and
- equal to 0 when \(P_1 = 0\).

One can check that the only linear function with this property is the function \(N \cdot P_1\). Thus, we arrive at the following recommendation:

How to gauge student’s knowledge: the resulting recommendation. When a student supplies his/her degree of confidence \(P_1\) in the answer \(A_1\) (and, correspondingly, the degree of confidence \(P_2 = 1 - P_1\) in the answer \(A_2\)), then we should give the student:
\begin{itemize}
\item $N \cdot P_1$ points if $A_1$ is the correct answer, and
\item $N \cdot P_2$ points if $A_2$ is the correct answer,
\end{itemize}
where $N$ is the number of points that the student would get for an absolutely correct answer with confidence 1.

**Discussion.** Let us show that if we follow the above recommendation, then we assign different numbers of grades in two situations that we wanted to distinguish:

\begin{itemize}
\item the bad situation in which a student is absolutely confident in the wrong answer $p_1 = 0$ and $p_2 = 1$, and
\item a not-so-bad situation when a student is ignorant but understands his or her ignorance and assigns the degree of confidences $p_1 = p_2 = 0.5$ to both possible answers.
\end{itemize}

Indeed:

\begin{itemize}
\item In the first (bad) situation, the student gets the smallest number of points: 0.
\item In the second, not-so-bad situation, the student gets $N \cdot 0.5$ points, which is more than 0.
\end{itemize}

**III. General Case**

**What if a question has several possible answers: analysis of the problem.** In general, a question can have several possible answers corresponding to several alternatives. Let us denote these alternatives by $A_1, \ldots, A_s$.

In this case, a student assigns, to each of these alternatives $A_i$, his/her degree of certainty $P_i$. Since we know that exactly one of the given $s$ alternatives is true, these probabilities should add up to 1: $\sum_{i=1}^{n} P_i = 1$.

How does adding this student’s knowledge change the decision of $n$ experts? Similarly to the previous case:

\begin{itemize}
\item it may be that previously, the experts selected a wrong alternative, and the student’s knowledge can help select the correct alternative $A_1$;
\item it also may be that the experts selected the correct alternative, but the addition of the student’s statement will lead to the selection of a wrong alternative.
\end{itemize}

Let us describe this in detail.

Similarly to the case of two alternative, we can conclude that a group of experts selects an action corresponding to the alternative $A_{i_{0}}$ if the corresponding expected utility is larger than the expected utility of selecting any other action, i.e., if

$$\left( \sum_{j=1}^{s} p_j \cdot u_{i_{0},j} \right) - \left( \sum_{j=1}^{s} p_j \cdot u_{i,j} \right) \geq 0 \quad (4)$$

for all $i$, where $p_i$ is the estimate of the probability that the $i$-th alternative $A_i$ is true. Similarly to the case of two alternatives, we conclude that

$$p_i = \frac{1}{n} \cdot \sum_{k=1}^{n} p_{i,k},$$

where $n$ is the number of experts and $p_{i,k}$ is the estimate of the probability of the $i$-th alternative $A_i$ made by the $k$-th expert.

When we add, to $n$ original experts, the student as a new expert, with $p_{i,n+1} = P_i$, then the probabilities $p_i$ change to new values

$$p'_i = \frac{1}{n+1} \cdot \sum_{k=1}^{n+1} p_{i,k} = \frac{n}{n+1} \cdot p_i + \frac{1}{n+1} \cdot P_i.$$

Thus, the left-hand side of the inequality (4) has a change which is linear in terms of the degrees $P_1, \ldots, P_s$.

For each case when the addition of the student as a new expert changes the inequality between two expected utilities, the corresponding interval of possible values of the difference is small and thus, the resulting utility is proportional to the linear function of $P_i$ – and is, thus, linear as well.

The probability of each such change is very small, so the probability that the addition of a student can change two or more inequalities – i.e., that two changes can occur at the same time – can be estimated as the product of these two (or more) small numbers and can, therefore, be safely ignored.

In this approximation, the overall utility can be obtained by adding the probabilities of all such cases and is, therefore, also a linear function of the probabilities $P_i$:

$$u = u_0 + \sum_{i=1}^{s} a_i \cdot P_i.$$

Let $c$ be the index of the correct answer, then this formula can be reformulated as

$$u = u_0 + u_c \cdot P_c + \sum_{i \neq c} a_i \cdot P_i. \quad (5)$$

Usually, there are no a priori reasons why one incorrect answer is better than another incorrect answer. So, it is natural to assume that the utility $c_i$ corresponding to each incorrect answer $A_i$ is the same. Let us denote this common value of the utility by $f$. Then, the above formula (5) takes the form

$$u = u_0 + u_c \cdot P_c + f \cdot \sum_{i \neq c} P_i. \quad (6)$$

Since the degrees $P_i$ add up to 1, we have

$$P_c + \sum_{i \neq c} P_i = 1,$$

hence

$$\sum_{i \neq c} P_i = 1 - P_c,$$

and the formula (6) takes the form

$$u = u_0 + u_c \cdot P_c + f \cdot (1 - P_c).$$

Thus, the utility is a linear function of the student’s degree of confidence $P_c$ in the correct answer.

Let us denote by $N$ the number of points that we assign to a correct answer in which the student is fully confident ($P_c = 1$). Naturally, a student gets 0 points when he or she is fully confident in the wrong answer (i.e., $P_i = 1$ for some $i \neq c$ and thus, $P_c = 0$). Thus, the desired linear function
should be equal to $N$ when $P_c = 1$ and to 0 when $P_c = 0$. There is only one such linear function: $N \cdot P_c$. So, we arrive at the following recommendation.

**What if there are several possible answers: the resulting recommendation.** Let $A_1, \ldots, A_s$ be possible answers, out of which only one answer $A_t$ is correct. Let $N$ denote the number of points that a student would get for a correct answer in which he or she is absolutely confident.

During the test, the student assigns, to each possible answer $A_t$, his/her degree of confidence $P_t$ that this answer is correct. These degrees must add up to 1: $\sum_{i=1}^{s} P_i = 1$.

Our analysis shows that for this, we give the student $N \cdot P_c$ points, where $P_c$ is the student’s degree of confidence in the correct answer.

**How do we combine grades corresponding to different problems?** In the above text, we describe how to assign number of points to a single question. Namely:

- Our idea was to assign the number of points which is proportional to the gain in expected utility that the student’s answer can bring in a real decision making situation.
- Our analysis has shown that this expected utility is proportional to the probability $P_1$ of the correct answer.
- Thus, our recommendation is to assign the number of points proportional to the probability of the correct answer.

Real-life tests usually have several questions.

- In the traditional setting, a student provides answers to each of these questions.
- In the new setting, for each question, the student also provides us with his/her degrees of confidence in different possible answers to this question.

How do we gauge the student knowledge level based on all this information?

A natural idea is – similarly to the case of a single question – to use, as the measure of the student’s knowledge, the expected utility that the student’s answers can bring in a real decision making situation. Let us show how this idea can be applied.

The general decision making situation means selecting a decision for each of the problems. For example, on a medical exam, a student may be asked several questions describing different patients.

Usually, different questions on the test are independent from each other. It is known (see, e.g., [2]) that if a decision problem consists of several independent decisions, then the utility of each combination of selections is equal to the sum of the corresponding utilities.

We know the utility corresponding to each question – this is the value that we used as a recommended grade for this particular question. Thus, the overall grade for the test should be equal to the sum of the grades corresponding to individual questions.

Hence, we arrive at the following recommendation.

**IV. Resulting Recommendation**

Let us consider a test with $T$ questions $q_1, \ldots, q_T$. For each question $q_t$, a student is given several possible answers $A_{t,1}, A_{t,2}, \ldots$. For each question $q_t$, we know the number of points $N_t$ corresponding to the answer which is correct and for which the student has a full confidence.

The student is required, for each question $q_t$ and for each possible answer $A_{t,c}$, to provide his/her degree of confidence $P_{t,c}$ that this particular answer is correct. For each question $q_t$, these probabilities should add up to 1:

$$P_{t,1} + P_{t,2} + \ldots = 1.$$

To estimate the student’s level of knowledge, we need to know, for each question $q_t$, the correct answer; let us denote this correct answer by $A_{t,c(t)}$. Then:

- for each question $q_t$, we give the student $P_{t,c(t)} \cdot N_t$ points;
- as an overall grade $g$, i.e., as a measure of overall student knowledge, we take the sum of the points given for individual problems: $g = \sum_{t=1}^{T} P_{t,c(t)} \cdot N_t$.
