Keywords: fuzzy control, nonlinear transformation, optimality

Abstract

In a series of papers and a book, M. Margaliot and G. Langholz proposed a hyperbolic approach to fuzzy control, in which they apply a certain hyperbolic non-linear transformation to the original variables. In this paper, we consider all possible non-linear transformations of this type and show that this hyperbolic transformation is indeed optimal.

1 Introduction

Many Practical Control Situations Can Be Adequately Described by Linear Systems. One of the main problems to which control is applied is stabilizing a plant. In this case, it is usually sufficient to consider only small deviations from the ideal state (if the deviations become large, this means that we are no longer in control). For the same reason, it is sufficient to consider only small values of control. These restrictions are known to simplify the resulting mathematics.

Indeed, assume that a state **s** is described by n numbers: $\mathbf{s} = (s_1, \ldots, s_n)$. Let's denote the ideal state by $(s_1^{(0)}, \ldots, s_n^{(0)})$. Instead of s_i , we can use new variables $x_i = s_i - s_i^{(0)}$ to describe a state. The advantage of using new variables is that now, a stable state is described as $(0, 0, \ldots, 0)$.

In general, the evolution of a state **x** under a control $\mathbf{u} = (u_1, \dots, u_p)$ is described by a system of differential equations

$$\dot{x}_i = E_i(x_1, \dots, x_n, u_1, \dots, u_p),\tag{1}$$

where the functions E_i are, in general, non-linear. Since we are considering states that are close to the equilibrium $(0, \ldots, 0)$ (i.e., we are considering small values of x_i), and small values of control, we can expand the functions E_i into Taylor series, and leave only the main (linear) terms. As a result, we get a linear system of differential equations:

$$\dot{x}_i = \sum_{j=1}^n a_{ij} \cdot x_j + \sum_{k=1}^p b_{ik} \cdot u_k, \tag{2}$$

where $\mathbf{A} = ||a_{ij}||$ and $\mathbf{B} = ||b_{ik}||$ are matrices.

For such linear systems, there exist well-developed optimal control techniques; see, e.g., [3]

In Many Other Practical Problems, Non-Linear Terms Must Be Taken Into Consideration. In many practical problems, before we achieve the desired trajectory, we must first reach it from the original state. On this stage, the deviations x_i of the actual state from the desired one are not necessarily small, so we no longer can neglect non-linear terms in the dependence of E_i on x_1, \ldots, x_n ; we must take non-linear terms into consideration.

If we do not take these terms into consideration, the linear description (2) stops being adequate. From the physical viewpoint, one of the main inadequacies of a linear representation is that it assumes the linear dependence between the deviation x_i and its rate of change: the larger the deviation x_i , the more it changes (i.e., the larger its rate \dot{x}_i). For example, in a linear system, if we increase x_i twice, we double the rate. Similarly, if we have proportionally larger deviations, all we have to do is proportionally increase the control values. Real-life systems are not that simple. In most practical systems, there is a limitation on the rate of change, due to which, e.g., no matter how large the control values are, we never exceed a certain influence level.

The existence of such bounds is in perfect agreement with common sense. For example, when we try to accelerate a car, at first, the more we press the accelerator, the faster the car moves; however, after a certain level, when we reach this particular car's limit, further pressing does not make the car go faster.

Nonlinear Control Problems Are, In General, Computationally Difficult. How can we control non-linear systems? In contrast to linear systems (for which optimal control can be easily computed by known formulas), for non-linear systems, no such easily computable general formulas exist. Moreover, the problem of the optimal control of a non-linear system is known to be computationally intractable (NP-hard); see, e.g., [1, 7].

Since it is computationally difficult to find the optimal control for an arbitrary nonlinear control system, it is desirable to look for suboptimal ("good enough") methods. A natural approach to finding such suboptimal controls is to find a class of systems for which there are explicit formulas for optimal control, and then approximate the actual nonlinear system by an appropriate system from this class. Then, the optimal control to an approximating system can serve as a suboptimal control to the original hard-to-solve nonlinear control system.

This idea is exactly what we do when we approximate the original nonlinear system by its linear approximation. So, what we really want is to find a class of nonlinear systems, a class which is more general than the class of linear system, and which will still allow us to have explicit expressions for optimal control.

Saturation Approach to Nonlinear Control: Main Idea. Since one of the main features of the real-life system which is not reflected in a linear-system description is saturation, a natural idea is to replace the original linear equations (2) with a new system of equations:

$$\dot{x}_i = \sum_{j=1}^n a_{ij} \cdot z_j + \sum_{k=1}^p b_{ik} \cdot u_k,$$
(3)

where $z_i = f_i(x_i)$, and the non-linear transformations $f_i(x)$ are selected in such a way that when even the values x_i tend to infinity, the new variables z_i stay within a limited range.

It is reasonable to start with the simplest possible implementation of this saturation idea, when we use the same non-linear function f(x) for all the variables x_i . To be more precise, we should take into consideration the fact that different components of the state vector (x_1, \ldots, x_n) represent different physical quantities (e.g., location and speed), so different measuring units can be used for different components. When we change a measuring unit, the numerical value of the measured quantity gets changed by a multiplicative constant $x_i \to k_i \cdot x_i$. Thus, "the use of the same function f(x)" can be formally described as using the new variables $z_i = f(k_i \cdot x_i)$ for some constants k_i .

For small x, the linear system representation works just fine, and no non-linear transformation is needed. Therefore, a natural requirement on the function f(x) is that for small values $x \approx 0$, we should have $f(x) \approx x$, and the closer we are to 0, the better this approximation. In precise terms, we should have f(x) = x + o(x).

Also, since we have no a priori reason to prefer positive or negative values of x, it is reasonable to make this non-linear transformation sign-independent, i.e., independent with respect to $x \to -x$. In more precise terms, we require that f(-x) is exactly the same as -f(x).

Hyperbolic Approach to Nonlinear Control and Its Relation to Fuzzy Control. In [8, 9], it was proposed to use $f(x) = \tanh(x)$. It turns out that not only this selection leads to a good quality control, but that the resulting optimal control coincides with a specific case of fuzzy control and thus, provides a commonsense interpretation of the corresponding optimal control.

Which Nonlinear Transformation Is The Best? Open Problem. The original linear model corresponds to the selection of a function f(x) = x. Since switching from f(x) = x to $f(x) = \tanh(x)$ drastically improves the control quality, it is natural to ask: will other choices of a transformation f(x) provide even better control results? And the final question: Which non-linear transformation is the best?

In this paper, we will give an answer to both questions by showing that the hyperbolic transformation is indeed the best (in some reasonable sense).

2 Towards Formulation of the Problem in Precise Terms

Why Is This Problem Difficult? We want to find a transformation function f(x) for which some characteristics J of the resulting control, such as average relaxation time or the average computation time, is optimal (in these cases minimal). The problem is that even for the hyperbolic function f(x), we do not know how to compute any of these possible characteristics. How can we find f for which J(f) is optimal if we cannot compute J(f) even for a single f? At first glance, there does not seem to be a likely answer.

However, we will show that this problem is solvable (and give the solution) using advanced math, namely, group theory.

First Comment: We Must Choose a Family of Functions, Not a Single Function. At first glance, our goal is to select the best transformation function f(x). We speak about choosing the transformation function f(x), but the expression for f(x) will change if we change the measuring unit for time.

If we change a unit used to measure time by a one which is k times larger, then the numerical value of time will decrease by k, and the numerical values of the rate of increase \dot{x}_i will increase by k. Thus, instead of the original term $z_i = f(x_i)$, we now have the term $k \cdot f(x_i)$. So, this change of a time unit is equivalent to using, instead of the original transformation function f(x), a new transformation function $k \cdot f(x)$. Since we did not change anything neither in the actual system nor in the control, all we did was change the measuring unit for time, the quality of a control cannot change. Thus, if the transformation function f(x) provided the optimal control, so would the transformation function $k \cdot f(x)$ which represents exactly the same control.

Hence, we cannot select a unique transformation function f(x) and claim it to be the best, because for every function f(x), the function $k \cdot f(x)$ leads to a control of exactly the same quality.

In other words, different transformation functions can be naturally grouped into families of functions so that different functions form the same family represent the same transformation, but in different units. In particular, if a function f(x) belongs to a certain family, then this family must also contain the function $k \cdot f$ for positive real numbers k – this corresponds to changing a time unit. (As we will see later, we can have other re-scalings which lead to the appearance of even more functions in the same family.)

In view of this family structure, instead of formulating a problem of choosing the best transformation function, it is more natural to formulate a problem of choosing the best family of functions.

What other transformations enable us to stay within the same family? To answer this question, let us recall that one of the most natural examples of a state variable x_i is a spatial coordinate. In this case, the derivative \dot{x}_i is a velocity. The numerical value of the velocity changes not only if we change the time unit (as we did before), but also if we go from the original coordinate system to a new inertial coordinate system which moves with respect to the original one with the constant speed. (The fact that we can express any physical law in terms of the moving system as well as in terms of the original immobile system was known as early as Galileo; it is one of the main principles behind Einstein's Relativity Theory.)

In Newtonian physics, when we move to a moving system, all the velocity values are changed by an additive constant. Thus, in terms of the transformation function, the possibility to use the moving system is equivalent to replacing the original function f(x) by a new function f(x) + c.

Hence, the functions f(x) and f(x) + c express the same transformation and the same control – but expressed in different coordinate systems. Therefore, if a family of physically equivalent transformation

functions contains a transformation function f(x), this family must also contain functions f(x) + c for all possible constants c.

Since we are talking about non-linear systems, we can also assume that some non-linear "rescaling" transformations $x \to g(x)$ are also applicable, i.e., the family may include the composition g(f(x)) for each of functions f(x). For example, according to relativity theory, turning to a new coordinate system which moves with a constant velocity v_0 with respect to the old one means that we replace each original velocity v by a new value

$$v' = \frac{v + v_0}{1 + \frac{v \cdot v_0}{c^2}}.$$

This change is non-linear in v and thus, corresponds to a non-linear change in the transformation function f(x) (which expresses the velocity $v = \dot{x}$).

It is reasonable to assume that there is some finite-parametric family of re-scalings, and that each family is obtained from a single transformation function f(x) by applying all these rescalings.

If $z \to g_1(z)$ and $z \to g_2(z)$ are possible rescalings, then it is natural to require that this composition $z \to g_1(g_2(z))$ and the inverse $z \to g_1^{-1}(z)$ are also possible rescalings (by g_1^{-1} we denoted an inverse function $g_1^{-1}(z) = w$ if and only if $g_1(w) = z$). In mathematical terms, this requirement can be expressed by saying that the class of possible rescalings is *closed* under composition and inverse. Such a class is called a *group*. Thus, we conclude the following:

A family is obtained by applying, to some transformation function f(x), all rescalings from some finitedimensional group G which includes all linear transformations (and maybe some non-linear ones).

From the physical viewpoint, if we have two different rescalings, there must be a smooth transition between them. In mathematical terms, the existence of this continuous transition is expressed by saying that the group is *connected*, and the fact that both the transformations and the transitions are smooth is expressed by saying that this is a *Lie group* (for a description in the context of computer science and fuzzy, see, e.g., [10]).

Which Family Is the Best? Among all such families, we want to choose the best one. In formalizing what "the best" means we follow the general idea outlined in [10]. The criteria to choose may be computational simplicity, average relaxation time, or something else.

In mathematical optimization problems, numerical criteria are most frequently used, when to every alternative (in our case, to each family) we assign some value expressing its performance, and we choose an alternative (in our case, a family) for which this value is the largest. However, it is not necessary to restrict ourselves to such numerical criteria only.

For example, if we have several different families that have the same average relaxation time T, we can choose between them the one that has the minimal computational complexity C. In this case, the actual criterion that we use to compare two families is not numerical, but more complicated: a family F_1 is better than the family F_2 if and only if either $T(F_1) < T(F_2)$ or $T(F_1) = T(F_2)$ and $C(F_1) < C(F_2)$. A criterion can be even more complicated. What a criterion must do is to allow us for every pair of families to tell whether the first family is better with respect to this criterion (we'll denote it by $F_1 > F_2$), or the second is better $(F_1 < F_2)$ or these families have the same quality in the sense of this criterion (we'll denote it by $F_1 > F_2$ and $F_2 > F_3$ then $F_1 > F_3$.

Another natural demand is that this criterion must choose a *unique* optimal family (i.e., a family that is better with respect to this criterion than any other family). The reason for this demand is very simple.

If a criterion does not choose any family at all, then it is of no use.

If several different families are "the best" according to this criterion, then we still have a problem to choose among those "best". Therefore, we need some additional criterion for that choice. For example, if several families turn out to have the same average relaxation time, we can choose among them a family with minimal computational complexity. So what we actually do in this case is abandon that criterion for which there were several "best" families, and consider a new "composite" criterion instead: F_1 is better than F_2 according to this new criterion if either it was better according to the old criterion or according to the old criterion they had the same quality and F_1 is better than F_2 according to the additional criterion. In other

words, if a criterion does not allow us to choose a unique best family it means that this criterion is not final; we have to modify it until we come to a final criterion that will have that property.

The next natural condition that the criterion must satisfy is connected with the fact that the numerical value of a variable x_i depends on the choice of the starting point. We have already mentioned that in Newtonian physics, when we turn to a moving coordinate system, the numerical value of the velocity changes by an additive constant: $v \to v' = v + c$. Previously, we applied this fact to the situation when one of the state variables was a spatial coordinate. However, when we express Newton's laws in terms of first-order differential equations (1), it is not enough to have spatial coordinates as state variables; we must also have velocities as state variable. (In this case, the typical Newton's law $\ddot{x} = F(x)$ can be expressed as $\dot{x} = v$ and $\dot{v} = F(x)$.) For such state variables, a new coordinate system means changing x by x + c. Since the acceleration \ddot{x} does not change under such change, this change means, in terms of a transformation function f(x), that we replace f(x) with f(x + c).

Since this change is simply a change in a coordinate system, it does not change the actual system or its control, it is reasonable to require that going from f(x) from f(x+c) should not change the relative quality of the transformation functions, i.e., if a family $\{f(x)\}$ is better that a family of $\{g(x)\}$, then for every c, the family $\{f(x+c)\}$ must be still better than the family $\{g(x+c)\}$.

So, we arrive at the following definitions.

3 Definitions and the Main Result

Definition 1.

- By a rescaling we mean a smooth (differentiable) function from real numbers into real numbers.
- By an appropriate rescaling group G we mean a finite-dimensional connected Lie group of transformations.
- By a family of functions we mean the set of functions that is obtained from a smooth (everywhere defined) non-constant function f(x) mapping the real line into a bounded interval by applying all the transformations from some appropriate rescaling group G. Let us denote the set of all the families by \mathcal{F} .
- A pair of relations $(<, \sim)$ is called consistent [10] if it satisfies the following conditions: (1) if a < b and b < c then a < c; (2) $a \sim a$; (3) if $a \sim b$ then $b \sim a$; (4) if $a \sim b$ and $b \sim c$ then $a \sim c$; (5) if a < b and $b \sim c$ then a < c; (6) if $a \sim b$ and b < c then a < c; (7) if a < b then b < a or $a \sim b$ are impossible.
- Assume a set A is given. Its elements will be called alternatives. By an optimality criterion we mean a consistent pair $(<, \sim)$ of relations on the set A of all alternatives. If a > b, we say that a is better than b; if $a \sim b$, we say that the alternatives a and b are equivalent with respect to this criterion.
- We say that an alternative a is optimal (or best) with respect to a criterion $(<, \sim)$ if for every other alternative b either a > b or $a \sim b$.
- We say that a criterion is final if there exists an optimal alternative, and this optimal alternative is unique.
- Let c be a real number. By the c-shift $T_c(f)$ of a function f(x) we mean a function $(T_c(f))(x) \stackrel{\text{def}}{=} f(x+c)$.
- By the c-shift $T_c(F)$ of a family F, we mean the set of the functions that are obtained from $f \in F$ by c-shift.

In this paper, we consider optimality criteria on the set \mathcal{F} of all families.

Definition 2. We say that an optimality criterion on F is shift-invariant if for every two families F and G and for every number c, the following two conditions are true:

- i) if F is better than G in the sense of this criterion (i.e., F > G), then $T_c(F) > T_c(G)$;
- ii) if F is equivalent to G in the sense of this criterion (i.e., $F \sim G$), then $T_c(F) \sim T_c(G)$.

As we have already remarked, the demands that the optimality criterion is final and shift-invariant are quite reasonable. The only problem with them is that at first glance they may seem rather weak. However, they are not, as the following Theorem shows:

Theorem. If a family F is optimal in the sense of some optimality criterion that is final and shift-invariant, then every transformation function f from this optimal family F which has the properties f(x) = x + o(x) and f(-x) = -f(x) is equal to $f(x) = a \cdot \tanh(x/a)$ for some real number a.

Since we use the transformation f(x) to generate values $c \cdot f(k \cdot x)$, the use of $\tanh(x/a)$ is equivalent to the use of the transformation function $\tanh(x)$. Thus, our theorem says, in effect, that for every reasonable criterion, among all non-linear transformation functions, the hyperbolic function is indeed optimal.

4 Proof

This proof is similar to the proofs given in [6, 10] that a similar function is the optimal activation function for neural networks.

1. We have defined G as a connected finite-dimensional Lie group of rescalings of the set of real numbers R onto itself that contains all linear transformations. For an n-dimensional space with arbitrary n, this classification was obtained in [4, 12].

In our case (when n = 1) the only possible groups are the group of all linear rescalings and the group of all fractionally-linear rescalings $x \to (ax + b)/(cx + d)$. In both cases, the group consists only of fractionally linear functions (the simplified proof for the 1-dimensional case is given in [10]).

2. Let us now prove that the optimal family F_{opt} exists and is shift-invariant in the sense that $F_{opt} = T_c(F_{opt})$ for all real numbers c.

Indeed, we assumed that the optimality criterion is final, therefore there exists a unique optimal family F_{opt} . Let's now prove that this optimal family is shift-invariant. The fact that F_{opt} is optimal means that for every other F, either $F_{opt} > F$ or $F_{opt} \sim F$. If $F_{opt} \sim F$ for some $F \neq F_{opt}$, then from the definition of the optimality criterion we can easily deduce that F is also optimal, which contradicts the fact that there is only one optimal family. So for every F either $F_{opt} > F$ or $F_{opt} = F$.

Take an arbitrary c and let $F \stackrel{\text{def}}{=} T_c(F_{opt})$. If $F_{opt} > F = T_c(F_{opt})$, then from the invariance of the optimality criterion (condition ii) we conclude that $T_{-c}(F_{opt}) > F_{opt}$, and that conclusion contradicts the choice of F_{opt} as the optimal family. So $F_{opt} > F = T_c(F_{opt})$ is impossible, and therefore $F_{opt} = F = T_c(F_{opt})$, i.e., the optimal family is really shift-invariant.

3. Let us now deduce the actual form of the functions f from the optimal family.

If f(x) is such a function, then the result f(x+c) of shifting this function f(x) by c belongs to $T_c(F)$, and so, due to Part 2 of this proof, it belongs to F. But all the functions from the family F can be obtained from each other by fractionally linear transformations, so $f(x+c) = (A+B\cdot f(x))/(C+D\cdot f(x))$ for some A, B, C, and D. So, we arrive at a functional equation for f. Let us reduce this equation to a one with a known solution. For that purpose, let us use the fact that fractionally linear transformations are projective transformations of a line, and for such transformations the cross ratio is preserved (see, e.g., [2], Section 2.3), i.e., if $g(x) = (A+B\cdot f(x))/(C+D\cdot f(x))$, then

$$\frac{g(x_1) - g(x_3)}{g(x_2) - g(x_3)} \cdot \frac{g(x_2) - g(x_4)}{g(x_1) - g(x_4)} = \frac{f(x_1) - f(x_3)}{f(x_2) - f(x_3)} \cdot \frac{f(x_2) - f(x_4)}{f(x_1) - f(x_4)}$$

for all x_i . In our case this is true for g(x) = f(x+c), therefore for all c the following equality is true:

$$\frac{f(x_1+c)-f(x_3+c)}{f(x_2+c)-f(x_3+c)} \cdot \frac{f(x_2+c)-f(x_4+c)}{f(x_1+c)-f(x_4+c)} = \frac{f(x_1)-f(x_3)}{f(x_2)-f(x_3)} \cdot \frac{f(x_2)-f(x_4)}{f(x_1)-f(x_4)}$$

The most general continuous solutions of this functional equation are given by Theorem 2.3.2 from [2]: either f is fractionally linear, or $f(x) = (a + b \cdot \tan(k \cdot x))/(c + d \cdot \tan(k \cdot x))$ for some a, b, c, d, and k, or $f(x) = (a + b \cdot \tanh(k \cdot x))/(c + d \tanh(k \cdot x))$.

Fractionally linear functions can be excluded because they do not map the real line into a bounded set. Similarly, we must exclude expressions with tangents. Thus, hyperbolic tangent is the only case left. Since we want f(x) = x + o(x) for x > 0, we thus must have a = 0; The requirement that f(-x) = -f(x) leads to d = 0. The theorem is proven.
